1 Tail Calls

Scheme implements tail-call optimization, which allows programmers to write recursive functions that use a constant amount of space. A **tail call** occurs when a function calls another function as its last action. As the tail call is the last action for the current frame, Scheme won't make any further variable lookups in the frame. Therefore, the frame is no longer needed, and we can remove it from memory.

Consider this version of factorial that does *not* use tail calls:

```
(define (fact n)
  (if (= n 0) 1
          (* n (fact (- n 1)))))
```

The recursive call occurs in the last line, but it is not the last expression evaluated. After calling (fact (-n 1)), the function still needs to multiply that result with n. The final expression that is evaluated is a call to the multiplication function, not fact itself. Therefore, the recursive call is *not* a tail call.

However, we can rewrite this function using a helper function that remembers the temporary product that we have calculated so far in each recursive step.

fact-tail makes single recursive call that is the last expression to be evaluated, so it is a tail call. Therefore, fact-tail is a tail recursive process. Tail recursive processes can

take a constant amount of memory because each recursive call frame does not need to be saved. Our original implementation of fact required the program to keep each frame open because the last expression multiplies the recursive result with n. Therefore, at each frame, we need to remember the current value of n.

In contrast, the tail recursive fact-tail does not require the interpreter to remember the values for n or prod in each frame. Once a new recursive frame is created, the old one can be dropped, as all the information needed is included in the new frame. Therefore, we can carry out the calculation using only enough memory for a single frame.

1.1 Identifying tail calls

A function call is a tail call if it is in a **tail context**. We consider the following to be tail contexts:

- the last sub-expression in a lambda's body
- the second or third sub-expression in an if form
- any of the non-predicate sub-expressions in a cond form
- the last sub-expression in an and or an or form
- the last sub-expression in a begin's body

2 Questions

1. For each of the following functions, identify whether it contains a recursive tail call. Also indicate if it uses a constant number of frames.

Solution: In the recursive case, the last expression that is evaluated is a call to +. Therefore, the recursive call is not in a tail context, and each of the frames remain active. This function uses $\Theta(n)$ frames.

```
(define (question-b x y)
  (if (= x 0)
          y
          (question-b (- x 1) (+ y x))))
```

Solution: The if form is in a tail context, and the recursive call is the third subexpression, so it is also in a tail context. Therefore, the last evaluated expression is the recursive function call. This function therefore uses $\Theta(1)$ frames.

```
(define (question-c x y)
  (if (> x y)
          (question-c (- y 1) x)
          (question-c (+ x 10) y)))
```

Solution: The recursive calls are the second and third sub-expressions of the if form. Therefore, only one of the calls is actually evaluated, and it is the last expression evaluated in each recursive call. This function therefore uses $\Theta(1)$ frames.

```
(define (question-d n)
  (if (question-d n)
          (question-d (- n 1))
          (question-d (+ n 10))))
```

Solution: Both of the recursive calls are in a tail context, so they are both tail calls. However, the if predicate, (question-d n), is another recursive call. This recursive call is not in a tail context, so this function does not use a constant number of frames.

2. Write a tail recursive function that returns the nth fibonacci number. We define fib(0) = 0 and fib(1) = 1.

```
(define (fib n)
```

3. Write a tail recursive function, reverse, that takes in a Scheme list and returns a reversed copy.

(**define** (reverse lst)

4. Write a tail recursive function, insert, that takes in a number and a sorted list. The function returns a sorted copy with the number inserted in the correct position.

```
(define (insert n lst)
```

3 Calculator

We are beginning to dive into the realm of interpreting computer programs – that is, writing programs that understand other programs. In order to do so, we'll have to examine programming languages in-depth. The *Calculator* language, a subset of Scheme, will be the first of these examples.

In today's discussion, we'll be implementing Calculator using regular Python.

The Calculator language is a Scheme-syntax language that includes only the four basic arithmetic operations: +, -, *, and /. These operations can be nested and can take varying numbers of arguments. Here's a few examples of Calculator in action:

```
> (+ 2 2)
4
```

```
> (- 5)
-5
> (* (+ 1 2) (+ 2 3))
15
```

Our goal now is to write an interpreter for this Calculator language. The job of an interpreter is to evaluate expressions. So, let's talk about expressions. A Calculator expression is just like a Scheme list. To represent Scheme lists in Python, we use Pair objects. For example, the list (+ 1 2) is represented as Pair ('+', Pair (1, Pair (2, nil))). The Pair class is similar to the Scheme procedure cons, which would represent the same list as (cons '+ (cons 1 (cons 2 nil))).

Pair is very similar to Link, the class we developed for representing linked lists. In addition to Pair objects, we include a nil object to represent the empty list. Both Pair instances and nil have methods:

- 1. __len__, which returns the length of the list.
- 2. __getitem__, which allows indexing into the pair.
- 3. map, which applies a function, fn, to all of the elements in the list.
- 4. to_py_list, which returns a Python list with the same elements.

Here's an implementation of what we described: class nil: """The empty list""" def len (self): return 0 def map(self, fn): return self nil = nil() # this hides the nil class *forever* class Pair: def __init__(self, first, second=nil): self.first, self.second = first, second def len (self): n, second = 1, self.second while isinstance(second, Pair): n, second = n + 1, second.second if second is not nil: raise TypeError("length attempted on improper list") return n def __getitem__(self, k): **if** k == 0: return self.first **if** k < 0: raise IndexError("negative index into list") elif self.second is nil: raise IndexError("list index out of bounds") elif not isinstance(self.second, Pair): raise TypeError("ill-formed list") return self.second[k-1] def map(self, fn): """Returns a Scheme list after applying Python function fn over self.""" applied = fn(self.first) if self.second is nil or isinstance(self.second, Pair): return Pair(applied, self.second.apply_to_all(fn)) else: raise TypeError("ill-formed list")

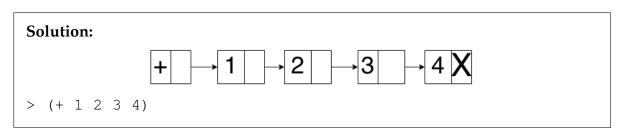

4 Questions

1. Translate the following Calculator expressions into calls to the Pair constructor.

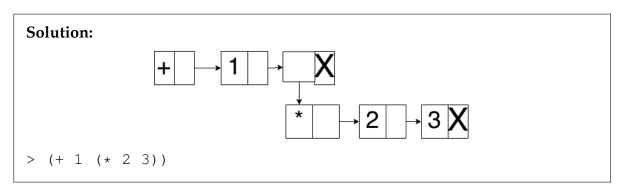

```
> (+ 1 2 (- 3 4))
```

2. Draw the box and pointer diagram and translate the following Python representation of Calculator expressions into the proper Scheme syntax:

```
>>> Pair('+', Pair(1, Pair(2, Pair(3, Pair(4, nil)))))
```

>>> Pair('+', Pair(1, Pair(Pair('*', Pair(2, Pair(3, nil))), nil)))

Evaluation discovers the form of an expression and executes a corresponding evaluation rule.

We'll go over two such expressions now:

- 1. *Primitive* expressions are evaluated directly. e.g. "1" just evaluates to itself.
- 2. *Call* expressions are evaluated in the same way you've been doing them by hand all semester:
 - (1) **Evaluate** the operator.
 - (2) Evaluate the operands from left to right.
 - (3) **Apply** the operator to the operands.

```
Here's calc_eval:
def calc_eval(exp):
    if not isinstance(exp, Pair): # primitive expression
        return exp
    else: # call expression
        # Step 1: evaluate the operator.
        operator = exp.first
        # Step 2: evaluate the operands.
        operands = exp.second
        args = operands.map(calc_eval).to_py_list()
    # Step 3: apply the operator to the operands.
    return calc_apply(operator, args)
How do we apply the operator? We'll dispatch on the operator name with calc_apply:
def calc_apply(operator, args):
    if operator == '+':
        return sum(args)
    elif operator == '-':
        if len(args) == 1:
            return -args[0]
        else:
            return args[0] - sum(args[1:])
    elif operator == '*':
        return reduce(mul, args, 1)
```

Depending on what the operator is, we can match it to a corresponding Python call. Each conditional clause above handles the application of one operator.

Something very important to keep in mind: calc_eval deals with **expressions** (in Calculator), calc_apply deals with **values** (which are in Python).

6 Questions

1. Suppose we typed each of the following expressions into the Calculator interpreter.

How many calls to calc_eval would they each generate? How many calls to calc_apply?

> (+ 2 4 6 8)

```
Solution:
5 calls to eval. 1 call to apply.

> (+ 2 (* 4 (- 6 8)))

Solution:
7 calls to eval. 3 calls to apply.
```

2. Alyssa P. Hacker and Ben Bitdiddle are also tasked with implementing the and operator, as in (and (= 1 2) (< 3 4)). Ben says this is easy: they just have to follow the same process as in implementing * and /. Alyssa is not so sure. Who's right?

Solution: Alyssa. We can't handle and in the apply step since and is a special form: it is short-circuited. We need to create a special case for it in calc_eval.

3. Now that you've had a chance to think about it, you decide to try implementing and yourself. You may assume the conditional operators (e.g. <, >, =, etc) have already been implemented for you.

```
Solution:
def calc_eval(exp):
    if not isinstance(exp, Pair):
        return exp
    elif exp.first == 'and':
        return eval_and(exp.second)
    else:
        ...
```

```
def eval_and(operands):
    curr = operands
    last = True
    while curr is not nil:
        last = calc_eval(curr.first)
        if last == False:
            return False
            curr = curr.second
    return last
```
